#### 155 Data availability statement

<sup>156</sup> The data supporting the results are attached in the Online Supplement.

## 157 Summary

Aim : Understanding mechanisms that maintain forest diversity under changing climate can benefit from the knowledge of traits that are closely linked to fitness. We tested whether the link between traits and seed number and seed size is consistent with two hypotheses, termed the leaf economics spectrum and the plant size syndrome, or if reproduction represents an independent dimension related to a seed size and number trade-off.

Location : The majority of the data comes from Europe, North and Central America, and East
 Asia. A majority of the data comes from South America, Africa, and Australia.

<sup>165</sup> **Time period** : 1960-2022.

<sup>166</sup> Major taxa studied : Trees.

Methods : We gathered 12 million observations of the number of seeds produced in 784 tree species. We estimated the number of seeds produced by individual trees and scaled it up to the species level. Next, we used PCA and Generalized Joint Attribute Modeling to map seed number and size on the tree traits spectrum.

: Incorporating seed size and number into trait analysis while controlling for environ-Results 171 ment and phylogeny with the GJAM exposes relationships in trees that might otherwise remain 172 hidden. Production of the large total biomass of seeds (product of seed number and seed size 173 hereafter species seed productivity, SSP) is associated with high leaf area, low foliar nitrogen, 174 low specific leaf area (SLA), and dense wood. Production of high seed numbers is associated 175 with small seeds produced by nutrient-demanding species with softwood, small leaves, and high 176 SLA. Trait covariation is consistent with opposing strategies, one fast-growing, early succes-177 sional, with high dispersal and the other slow-growing, stress-tolerant, that recruit in shaded 178 conditions. 179

Main conclusion : Earth system models currently assume that reproductive allocation is indifferent among plant functional types. Easily measurable seed size is a strong predictor of the seed number and species seed productivity. The connection of SSP with the functional traits can form the first basis of improved fecundity prediction across global forests.

# **Introduction**

<sup>189</sup> Understanding the mechanisms that promote and maintain forest tree diversity under a warming <sup>190</sup> climate can benefit from the knowledge of traits that are closely linked to fitness (Adler *et al.*,

2014; Paine et al., 2015; Yang et al., 2018; Kelly et al., 2021). Adaptive evolution operates on 191 the variation that affects survival and reproduction. Leaf traits, wood density, and plant height 192 are clearly important for trees, yet their connections to fitness are indirect (Wright et al., 2004; 193 Violle et al., 2007; Chave et al., 2009; Díaz et al., 2016). For example, large, thin, short-lived 194 leaves with high nitrogen content confer clear benefits in high-resource environments where 195 long-lived, highly lignified leaves are less advantageous (Shreve, 1925; Field & Mooney, 1986; 196 Reich, 2014). Fitness is the quantitative representation of individual reproductive success, an 197 organism's ability to pass its genetic material to its offspring. Thus, interpreting the fitness 198 implications of traits often requires broad extrapolation, such as ecophysiological measurements 199 describing minute-scale responses of leaves, roots, or xylem elements that are integrated with 200 many other responses to determine survival and/or reproduction over the lifetimes of whole 201 plants. While no trait links directly to fitness in trees, many are so weakly tied to fitness 202 that their utility for comparative studies remains uncertain. In that light, seedling recruitment 203 at tropical Barro Colorado Island provides a more direct link to fitness (Rüger et al., 2018, 204 2020). Nonetheless, given that recruitment varies for each species at each site, the species-level 205 reproductive effort could be a valuable extension for trait understanding. Only recently have 206 long-term and geographically extensive measurements of the number of seeds produced by trees 207 needed for species-level synthesis become available (Clark et al., 2021; Journé et al., 2022; Qiu 208 et al., 2022; Sharma et al., 2022). Here, we re-examine the hypotheses that describe the seed 209 number and size as part of an omnibus syndrome that explains all traits (e.g., fast-slow plant 210 economics spectrum) or, alternatively, as a separate axis of variation. 211

Principal components analysis (PCA) has been a primary tool for exploring combined trait 212 variation, contributing to at least three interpretations for forest trees. One view sees the number 213 of seeds produced and their size together with leaf traits as part of a "fast-slow" continuum 214 of plant strategies (Reich, 2014). That dimension represents the trade-off between resource 215 acquisition and processing, and it could be linked to a growth-survival trade-off (Poorter et al., 216 2008; Wright et al., 2010; Rüger et al., 2018). Cheaply constructed leaves that assimilate carbon 217 quickly, together with low wood density, characterize species that are resource-demanding, grow 218 fast, and die young (Westoby et al., 2002; Moles, 2018). In such species, the production of a 219 large number of seeds may offset mortality losses (Muller-Landau, 2010; Reich, 2014). Species 220 with some or all of these traits might dominate early successional stages through effective 221 colonization, and they might not persist under intense competition (Poorter et al., 2008; Wright 222 et al., 2010). 223

Alternatively, the size hypothesis suggests that the seed number and seed size is part of 224 a stature-recruitment trade-off (Kohyama, 1993; Díaz et al., 2016; Rüger et al., 2018, 2020). 225 According to this hypothesis, large plant size maximizes canopy performance at the expense 226 of recruitment, and vice versa. The analysis of 282 co-occurring tree species at tropical Barro 227 Colorado Island (BCI) emphasized a leaf-trait axis and a size-recruitment axis, with species 228 characterized by small stature, small leaves, and small seeds having high recruitment (Rüger 229 et al., 2018). Follow-up studies indicated that stature-recruitment trade-off extends to tropical 230 forests more generally Kambach et al. (2022). 231

Finally, seed number and seed size may represent a third, largely independent, dimension of variation, as proposed by the twin-filter (TF) hypothesis (Grime & Pierce, 2012). According to the TF, primary strategies such as fast-slow determine persistence for the climate/habitat norms, while traits involved in episodic events, which might include reproduction, affect fitness independent of other traits (Grime & Pierce, 2012; Pierce *et al.*, 2014). The leaf-height-seed (LHS) scheme of Westoby (1998) hypothesizes that seed size plays a role similar to reproduction in the TF model. In both hypotheses, plants can produce either many or few seeds (TF) or small or large seeds (LHS), largely independent of other plant traits. All three of the foregoing hypotheses imply an important role of seed number and seed size, and they assume that all traits have some connection to fitness. The availability of species-level seed numbers can lend novel insight to trait analysis due to its close connection to recruitment, a major demographic and fitness indicator.

A limitation of summaries available from PCA comes from the fact that correlations include 244 all the indirect ways that traits could be associated. For example, a correlation between seed size 245 and wood density could occur if there was a need for high wood density in order to produce large 246 seeds. If true, this would be a direct relationship. Alternatively, both variables might be driven 247 by climate for reasons that do not depend on one another. In such a case, that would be an indirect 248 relationship. Another indirect relationship is represented by phylogenic conservatism. Some 249 species groups tend to produce larger seeds or denser wood than others, even if environments that 250 might select for one or both traits change. The correlation structure exposed by PCA does not 251 discriminate between direct (conditional) and indirect (marginal) relationships. If relationships 252 are indirect, then conditional estimates offer the most transparent view of their connections 253 (Seyednasrollah & Clark, 2020). To quantify direct links between traits, the traditional study 254 with PCA is supplemented here with conditional relationships between traits using Generalized 255 Joint Attribute Modeling (GJAM) (Clark et al., 2017). Including environment as fixed effects 256 and phylogenetic groups as random effects, GJAM decomposes trait relationships into direct 257 and indirect relationships. While we believe GJAM is a valuable extension, we present results 258 of PCA as well to facilitate comparison with past studies. 259

**Figure 1:** Hypothetical associations between dimensions of plant life strategies represented by functional traits and the seed number, seed size, and species seed productivity (the product of seed number and seed size, SSP developed by Qiu *et al.* (2022)). Seed production can be associated with: A) fast life syndrome (slow-fast resource turnover axis); B) size syndrome; C) its own, largely independent axis of seed size-seed number trade-off. Both seed number and SSP are divided by tree basal area in our analyses.

In this study, we analyze trait syndromes in trees from a perspective that includes the number of seeds produced and seed size. The Masting Inference and Forecasting (MASTIF) network includes 12 million tree-year observations of the number of seeds produced by 775,991 trees from 784 species from a broad range of biomes (Journé *et al.*, 2022; Qiu *et al.*, 2022). To control for variation within species and, thus, to sharpen our understanding of interspecific differences, we estimate seed numbers produced by trees with an analytical framework that includes trees'

condition (species, size, shading), habitat (soils), and climate (temperature and moisture deficit),

while accommodating dependence between and within trees across years (Clark *et al.*, 2019).

This large sample size is important for the notoriously noisy seed production in trees (Kelly 268 et al., 2021), where tree-to-tree and year-to-year variation in seed number span several orders of 269 magnitude (Clark et al., 2004; Journé et al., 2022). By combining seed number with seed size into 270 species seed productivity (seed size x seed number, SSP, developed by Qiu et al. (2022)), we show 271 how reproductive traits relate to one another separately and in combination. Combining seed 272 number and seed size into SSP brings more exhaustive information on reproductive investment 273 because species that invest in large seeds are producing more seeds than expected from the 1:1 274 trade-off (Qiu et al., 2022). For this reason, SSP should be more strongly aligned with seed size 275 than seed number. By standardizing these metrics for the tree size we account for the variation in 276 size distribution within the data and facilitate comparisons. For example, the SSP is the average 277 annual species seed productivity per m2 basal area at average environmental conditions across 278 the species' range in the data (Qiu et al., 2021a, 2022). If large seeds confer an advantage in 279 competitive, shaded understories, while many small seeds allow colonization of distant sites, 280 then SSP provides a direct link to fitness. The hypothesized relationships between seed number, 281 seed size, SSP, and traits are summarized in Figure 1. 282

# 283 Methods

Seed number, species seed productivity (SSP) and MASTIF model Estimating the number 284 of seeds produced in perennial plants suffers from extreme signal-to-noise problem, created 285 by orders of magnitude variation from year to year and tree to tree (Pesendorfer et al., 2021; 286 Pearse et al., 2020; Clark et al., 2004) that can bury any trend (Clark et al., 2021). There are as 287 many time series as there are trees that must be modeled together because there is dependence 288 created by among-trees synchrony in masting variation (Crone et al., 2011; Bogdziewicz et al., 289 2021). Masting patterns are further complicated by the spatio-temporal variation in habitat and 290 climate (Pesendorfer et al., 2021; Pearse et al., 2020). The many sources of variation mean that 291 estimation of a seed number produced by trees can only be achieved from broad coverage and 292 large sample sizes while accounting for individual trees' condition, local habitat, and climate 293 (Clark et al., 2021; Qiu et al., 2021a; Sharma et al., 2022). This is here achieved with the 294 MASTIF model (Clark et al., 2019). 295

The MASTIF model and data from the MASTIF network are summarized here, and exten-296 sively described in recent papers (Clark et al., 2019, 2021; Qiu et al., 2021a; Sharma et al., 297 2022; Journé et al., 2022). The tree-year observations of seed numbers in the network come 298 from seed traps and from crop counts. Data include longitudinal (repeated) observations on 299 individual trees (99%) and opportunistic observations that come through the iNaturalist project 300 (Clark et al., 2019). Seed trap data consists of numbers of seeds that accumulate annually in 301 mapped seed traps on forest inventory plots. A fitted dispersal kernel relates seed counts to 302 mapped trees, accounting for uncertainty in seed transport and Poisson seed counts (Clark et al., 303 2019). Crop counts include counts of reproductive structures with estimates of the fraction of 304 the crop observed, and beta-binomial distribution accounts for uncertainty in the crop-fraction 305 estimates (Clark et al., 2019). This study includes 12,008,722 tree-years from North America, 306 South and Central America, Europe, Africa, Asia, and Oceania, which is gathered over 5,115 307 sites and 787,444 trees (Fig. 2). The MASTIF model jointly estimates the number of seeds 308 produced based on all the observations. The seed number (SN) and species seed productivity 309 (SSP) (Qiu et al., 2022) used in the analysis are calculated based on 297,690 mature individuals 310 and 3,730,381 tree-years. The MASTIF model uses the whole dataset to estimate seed numbers 311 produced annually, but the SN and SSP are calculated based on a mature tree subset of these 312 estimates. The list of species included in the analysis is given in the Online Supplement as a csv 313

314 file.

Figure 2: Map of raw data used to estimate the number of seeds produced by trees with the MASTIF model.

The MASTIF model, detailed in Clark et al. (2019), is a dynamic biophysical model for 315 year-to-year and tree-to-tree seed production. The MASTIF model is a Bayesian hierarchical, 316 state-space model that allows for conditional independence in crop-count and seed-trap data 317 through latent states. The model estimates the number of seeds produced with conditional 318 fecundity, which depends on the probability that the tree is sexually mature, tree size, shading 319 (five classes from full sun to full shade), local climate, and soil conditions. Random effects 320 on individual and year allow for wide variation between trees and over time that is typical of 321 seed production. The posterior covariance between trees and years can take any form, avoiding 322 assumptions of standard time-series models, important due to the quasiperiodic variation in time 323 and varying levels of synchronicity between individual trees (Pesendorfer et al., 2021). Model 324 structure and methodology were implemented with R, version 4.0 (R Core Team, 2020) and the 325 R package Mast Inference and Forecasting (MASTIF) (Clark et al., 2019). 326

Seed number and species seed productivity (SSP) at the tree and the species level The MASTIF model incorporates the effects of tree attributes with the environment on maturation and conditional fecundity. To allow for an uncertain identification of seeds from trees of the same genus and for dependence within trees over time and between trees, all three-years of a genus are modeled jointly (Clark *et al.*, 2019, 2021). For each tree *i* of species *s* at stand *j* in year *t*, the expected seed number is the product of maturation probability  $\hat{\rho}$  and conditional fecundity  $\hat{\psi}$ ,

$$E(f_{ijs,t}) = \hat{f}_{ijs,t} = \hat{\rho}_{ijs,t} \hat{\psi}_{ijs,t}$$
(1)

<sup>334</sup> Conditional fecundity depends on predictors, individual effects, year effects, and error,

$$log(\hat{\psi}_{ijs,t}) = \mathbf{x}'_{ijs,t} \boldsymbol{\beta}^{(x)} + \boldsymbol{\beta}^{(w)}_{ijs} + \boldsymbol{\gamma}_{g[ij]s,t} + \epsilon_{ijs,t}$$
(2)

where  $\mathbf{x}_{it}$  is a matrix holding individual attributes and environmental conditions (see *Generalized joint attribute modeling* below), and  $\boldsymbol{\beta}^{(x)}$  are fixed-effects coefficients.  $\beta_{ijs}^{(w)}$  is the random effect for tree *i* of species *s* at stand *j*.  $\gamma_{g[ij]s,t}$  are year effects that are random across groups *g* and fixed for the year *t* to account for interannual variation that is not fully captured by climate anomalies. Group membership for year effects (g[ij]s) is defined by species-ecoRegion (Clark *et al.*, 2019). There is a noise term  $\epsilon_{ijs,t}$ . Maturation probability  $\hat{\rho}_{ijs,t}$  accounts for the immature state (for small trees) and failed crop in larger trees. The model implementation is open-access with R package MASTIF, with algorithm details provided in Clark *et al.* (2019).

We estimated species investment into reproduction using two metrics, both scaled to the tree 343 basal area: annual seed number (SN), and annual species seed productivity (SSP; seed number 344  $\times$  seed mass) Qiu *et al.* (2022). Estimation of both SN and SSP starts with the estimation of 345 individual tree mean number of produced seeds that depends on each tree location that accounts 346 for effects of the environment and includes uncertainty for each year. Individual trees' number 347 of seeds produced over a species is then summarized as SN or SSP, as explained below. The 348 tree-level estimate of seed number, i.e., individual seed production (ISP), is the product of seed 349 size (its mass)  $m_s$  and seed number, scaled to tree basal area per year (Journé *et al.*, 2022). 350 We quantify ISP as the mass of a tree's seed production relative to its basal area to standardize 351 for tree size (intermediate trees produce more seeds than smaller ones Qiu et al. (2021a)). All 352 estimates are time averages across annual estimates, so we hereafter omit yr<sup>-1</sup> from dimensions. 353 Therefore, ISP has the units of  $g/m^2$ . Following Qiu *et al.* (2022), species seed productivity 354 (SSP) comes from the expectation of all ISP for a given species. The detailed calculations of 355 ISP and SSP are provided in Online Supplement. Analyses of SSP are done on the proportionate 356 (log) scale to avoid dominance of results by the few species that produce the highest seed number. 357 The seed number is estimated following the same steps, but the calculations omit seed size (mass 358 of individual seed). 359

**Traits** We selected six functional plant traits previously shown to capture plant life strategies 360 well (Díaz et al., 2016; Carmona et al., 2021): plant height (measured in m), leaf area (measured 361 in mm<sup>2</sup>), specific leaf area (SLA; measured in mm<sup>2</sup>/mg; the inverse of leaf mass per area), 362 leaf nitrogen concentration (measured in mg/g), wood density (measured in  $g/m^3$ ) and seed size 363 (measured in g). The data was obtained from primary sources and supplemented with publicly 364 available data from the latest version of the TRY Plant Trait Database TRY Plant Trait Database 365 (Kattge et al., 2020) extracted from the Carmona et al. (2021). Missing values for the six traits 366 were filled with genus-level means. Bivariate relationships are summarized in Fig. S4). 367

**Trait relationships** PCA summarizes correlation in the joint distribution of traits, written in bracket notation as  $[\mathbf{T}] = [T_1, ..., T_M]$ . If the relationship between traits depends on phylogeny, summarized by phylogenetic groups  $P_{g=1...G}$  (taxonomic, e.g., genus or family), and on the environment *X*, then there is a joint distribution  $[\mathbf{T}, P, X]$ . The indirect environment and phylogeny effects may dominate the relationships between some or many traits. An alternative approach uses conditional distribution,

$$[\mathbf{T}|P,X] = \frac{[\mathbf{T},P,X]}{[P,X]}$$
(3)

where the distribution of groups and environments [P, X] is that which occurs in the data set. 374 To determine trait relationships we fit a joint model to the conditional distribution  $[\mathbf{T}|P, X]$ , 375 which provides estimates of the phylogeny as random groups  $\mathbf{g}[s], g = 1, \dots, M$  for species s 376 and X as a  $O \times M$  matrix of coefficients **B** for O predictors of M traits. We then decompose 377 the distribution into (conditional) effects of other traits and the environment (Seyednasrollah & 378 Clark, 2020; Qiu *et al.*, 2021b). The effect of trait *m* on the remaining -m traits is the conditional 379 distribution  $[\mathbf{T}_{-m}|T_m, P, X]$ . Using the fitted model in GJAM (see below), we decompose the 380 conditional effect of *m* on other traits as, 38

$$E(\mathbf{T}_{-m}|T_m, P, X) = E(\mathbf{T}_{-m}|T_m) + E(\mathbf{T}_{-m}|P, X)$$
(4)

The first term is a conditional influence of m as distinct from (P, X).

**Generalized joint attribute modeling** To incorporate the effects of environment and phy-383 logeny on the distribution of traits, we use GJAM (Clark et al., 2016). Environmental covariates 384 include soil fertility (Cation Exchange Capacity), mean annual temperature, and annual ac-385 cumulative moisture deficit (difference between potential evapotranspiration and precipitation) 386 averaged at the species level for the MASTIF data set. GJAM allowed us to accommodate the 387 dependence between traits and phylogeny as random groups. A more detailed description of 388 GJAM fitting is given in Online Supplement. GJAM fitting is open-access with R package GJAM 389 on CRAN. 390

#### **391 Results**

Across the 784 species, foliar traits, wood density, and seed number and size are the dominant 392 sources of variation. In the principal components analysis (PCA) of our data that include 393 species seed productivity (SSP), 54.2% of variation is concentrated in two principal components 394 of equal importance (Fig. 3A, Fig. S1). PCA1 is associated with leaf traits. At one end are 395 species with thin, large, acquisitive leaves (large SLA, high area, high foliar nitrogen). Common 396 examples include heaven lotus (Gustavia superba), Panama tree (Sterculia apetala), pawpaw 397 (Asimina triloba), and eastern walnut (Juglans nigra). At the other end are species with low 398 SLA, low foliar nitrogen, and low leaf area, including evergreen conifers like giant sequoia 399 (Sequoiadendron giganteum), California redwood (Sequoia sempervirens), monkey puzzle tree 400 (Araucaria araucana), Fraser fir (Abies fraseri), and white cedar (Thuja occidentalis). PCA2 401 is dominated by seed size, SSP, and wood density. Large seeds are associated with high SSP 402 because species that produce large seeds tend to produce proportionally more of them than 403 predicted the strict trade-off between seed size and number (Qiu et al., 2022). Dense wood is 404 associated with both seed size and SSP, with examples including African crabwood (Carapa 405 procera) and Fagales such as chestnuts (*Castanea*) and oaks (*Quercus*). At the opposite end 406 with low-density wood and small seeds are willows (Salix), fuchsia (Fuchsia excorticata), and 407 trumpet tree (*Cecropia obtusa*). Tree height is weakly associated with foliar attributes: small 408 trees tend to have large, thin leaves. 409

A second PCA in which SSP is replaced with seed number yields similar results (Fig. S2). As with the PCA using SSP (fig. 3A), the first axis of this second PCA is associated with foliar traits with no contributions from seed numbers. The second PCA axis separates species according to seed size, seed number, and wood density. Tree height is again weakly associated with foliar attributes but also with reproduction: small trees tend to produce small seeds in large numbers (Fig. S2).

Using conditional prediction to control for the environment and taxonomic relatedness 416 shows that seed size is positively related to SSP and negatively related to seed number (Fig. 3B). 417 Conditional prediction allows for uncertainty and the effects of the environment on all traits, 418 but then isolates their direct (conditional) relationships to one another (see Methods). Nutrient-419 demanding species with high foliar nitrogen concentrations, high SLA, and low-density wood, 420 produce small seeds in high numbers, a relationship that is not apparent in PCA. Large seeds 421 are produced by trees with dense wood, few seeds, high leaf area, low foliar N, and low SLA 422 (Fig. 4B-G). The relationship between high SSP and dense wood is suggested by PCA (Fig. 423

**Figure 3:** Seed size, seed number, and species seed productivity (SSP) on the spectrum of tree form. A) Biplot; arrow length indicates the loading of each considered trait onto the first two PCA axes. Points represent the position of species, coded blue for the needle, black for broad-deciduous, and yellow for broad evergreen leaf habit. Larger points indicate means for the groups. An extended version of that graph is given in Fig. S1. B) Summary of GJAM coefficients presented in Fig. 4. Significant associations between traits are highlighted by lines, coded red for negative and blue for positive relationships. Dashed lines highlight associations that are significant only in the model without phylogenetical control (see Fig. S3). Extended PCA plots are available in supplement Fig. S2. SSP stands for species seed productivity and is the product of seed size × seed number (Qiu *et al.*, 2022). Both SSP and seed number are standardized to a tree basal area. Thicker lines qualitatively separate main relationships from the minute correlations among some foliar and other traits. Each trait has a unique color to improve comparisons between A and B.

<sup>424</sup> 3A), but that relationship is not significant after accounting for environment and phylogeny (Fig.

<sup>425</sup> 3B). Rather, the PCA can be driven by indirect links between traits. Although the links between <sup>426</sup> wood density and foliar traits are significant, they are weaker than the relationship between wood <sup>427</sup> density and seed size (Fig. 4D).

## 428 Discussion

Across 784 species spanning tropical to boreal environments, estimation of the number of seeds 429 produced by trees brings new insight to trait analysis with a strong connection to fitness. Seed 430 size and number make a dominant contribution to trait syndromes in trees, but one that is not 431 strictly consistent with the fast-slow or stature trade-offs. Controlling for common ancestry 432 and environment with GJAM indicates that large seed size is weakly associated with high leaf 433 area, low foliar nitrogen, low SLA, and dense wood. These associations were not detected by 434 conventional PCA that does not condition on environmental dependencies. Thus, there is a 435 weak, indirect link between these traits to SSP. Fast strategies, as captured by leaf traits, were 436 not coupled with high seed numbers, even though nutrient-demanding trees show a tendency to 437 produce small seeds. Seed size and number were also not associated with tree height as in the 438 stature-recruitment hypothesis at the tropical BCI (Rüger et al., 2018, 2020). Across all species 439 and sites in this study, trees with dense wood, large leaves, and low nutrient demands produce 440 large but few seeds. These species invest heavily in SSP. In contrast, a high seed number is 441

**Figure 4:** Conditional relationships between traits after accounting for climate and phylogeny. Posterior distributions are shown as boxes that contain median vertical lines and are bounded by 68% credible intervals (CI), with 95% CI whiskers. Coefficients are evaluated on a standardized scale. The inset plots at A highlight the relationships between species seed productivity (SSP) and other traits after removing the effects of seed number and seed size that are part of SSP. Insets at B and C are analogous. Fig. 3 summarizes the significant relationships. See Fig. S3 for conditional relationships derived from GJAM without the phylogenetical control. SSP stands for species seed productivity and is the product of seed size x seed number. Both SSP and seed number are standardized to a tree basal area.

associated with small seeds, most common in species with low-density wood, low leaf area, high
 foliar N, and high SLA.

Trait relationships identified here are consistent with some traditional trait concepts, in-444 cluding change of traits associated with species turnover through succession (Bazzaz, 1979; 445 Falster & Westoby, 2005; Wilfahrt et al., 2014). Production of a large number of small seeds 446 increases recruitment in distant, disturbed habitats (Muller-Landau, 2010). The r strategy of 447 the r-K spectrum is associated with fast growth and high nutrient requirements (Bazzaz, 1979; 448 Huston & Smith, 1987; Henery & Westoby, 2001; Muller-Landau et al., 2008). By including 449 seed size and number, our analysis indicates that the traditional r strategy, which might include 450 low-density wood that often comes with fast growth (Chave et al., 2009), also includes the 451 production of small seeds. High foliar nitrogen and cheap leaf construction (high SLA) align 452 with high photosynthetic rates (Reich & Oleksyn, 2004; Reich, 2014; Moles, 2018). On the 453 K side are species with dense wood and slow growth (Westoby, 1998; Poorter et al., 2005). 454 Low foliar nitrogen and low SLA can align with low foliar Rubisco content, low photosynthetic 455 capacity, and, thus, low maintenance respiration in low light (Reich et al., 1998; Poorter, 2015; 456 Moles, 2018). Species with such conservative leaves are also selected for large seeds needed 457 for seedling establishment in shade, at the expense of the many small seeds that would promote 458 colonization of distant sites (Westoby et al., 2002; Muller-Landau, 2010). 459

460 Species seed productivity (SSP) is more strongly driven by seed size than seed number, which

follows from the observation that the size-numbers trade-off in trees is not 1:1 (Qiu *et al.*, 2022). 461 Instead, species that produce large seeds more than compensate (on a mass basis) for fewer of 462 them, resulting in higher species seed productivity (Qiu et al., 2022)). Therefore, the estimates 463 of SSP for a given tree size, enrich the interpretation of plant reproductive strategies beyond the 464 insights that come from seed size alone (Westoby et al., 2002; Muller-Landau, 2010; Lebrija-465 Trejos et al., 2016). On one hand, the production of small, copious seeds increases recruitment 466 opportunities at the cost of limited investment per individual seed. Small seeds can mean low 467 abiotic stress tolerance in competitive sites (Westoby et al., 2002; Tilman, 1994; Fricke et al., 468 2019). On the other hand, large seeds come with a cost of producing fewer of them (Henery & 469 Westoby, 2001; Muller-Landau et al., 2008; Fricke et al., 2019), each with a greater investment 470 in seedling survival (Fricke et al., 2019; Muller-Landau et al., 2008). However, the high SSP 471 in species that produce large seeds means that such species are selected for proportionally high 472 total seed biomass investment per individual to maintain populations in low light conditions 473 (Kohyama et al., 2003; Falster & Westoby, 2005). In other words, the production of a large 474 number of seeds appears to generate a generally higher cost of reproduction. Testing whether 475 SSP is a better indicator of reproductive success than seed number or size alone appears a fruitful 476 avenue for future research. 477

The divergent results from this study and those suggesting a stature-recruitment trade-off 478 at tropical forests (Rüger et al., 2018, 2020; Guillemot et al., 2022; Kambach et al., 2022) are 479 not necessarily in conflict. The within-site covariation in traits, where short trees might be 480 associated with small seeds and leaves in the shaded understory (Rüger et al., 2018), does not 481 need to align with an among-site, species-level difference, which integrates over environments 482 for each species at many sites. Moreover, Rüger et al. (2018) measured the recruitment of 483 saplings, whereas our analysis includes seed numbers. In turn, the lack of relationship between 484 seed size and plant height reported by past studies (Díaz et al., 2016) may follow from the fact 485 that the GJAM models control for phylogeny, whereas PCA does not. This is supported by the 486 fact that both PCA and GJAM models that do not include shared ancestry indicate a positive 487 relationship between seed size and tree height. This, and other trait relationships, that are present 488 only in phylogenetically-controlled GJAM indicate that conditional prediction to control for the 489 environment and taxonomic relatedness may be a step forward for the subdiscipline. 490

Anticipating individual and combined effects of global change requires understanding the 491 vulnerability not only of mature trees but also of seed number and recruitment (Clark et al., 492 2021; Sharma et al., 2022; Qiu et al., 2021b; Bogdziewicz, 2022; Hanbury-Brown et al., 2022). 493 One major challenge, that exists in ecology more generally (Nuñez et al., 2021), is to increase 494 the data coverage to underrepresented regions such as Africa or Southeast Asia in our case. 495 Earth system models currently assume that reproductive allocation does not differ among plant 496 functional types (Scholze et al., 2006; Hanbury-Brown et al., 2022). There is area and promise 497 for improvement using functional trait data. A recent study at the BCI predicted forest succession 498 by replacing the hyper-diversity of tropical forests with just two trait axes associated with fast-499 slow and size dimensions (Rüger *et al.*, 2020). While the size of our seed production dataset 500 is unprecedented, seed number is much more difficult to measure due to its variable nature, as 501 compared to e.g. seed size. This could explain why we found stronger links between traits with 502 seed size. The good news is that the easily measurable seed size is a strong predictor of species 503 seed productivity (SSP) and seed number. The connection of SSP with the functional traits can 504 form the first basis of improved fecundity prediction across global forests. 505

## **Supplementary material**

This Supplement provides additional Methods descriptions and additional data summaries as
 tables and figures. Full summaries of the MASTIF network are available at these links for sites
 and species.

#### **Materials and Methods**

Individual seed productivity (ISP) and species seed productivity (SSP) Calculation of ISP combines posterior mean values with their uncertainties, as an expectation over the variations across years (tree *i* of species *s* at stand *j* in year *t*):

$$ISP_{ijs} = \frac{m_s}{b_{ij}} \times \frac{\sum_t w_{ijs,t} \hat{f}_{ijs,t}}{\sum_t w_{ijs,t}}$$
(1)

where  $m_s$  is seed size (g),  $b_{ij}$  is basal area ( $m^2$ ), and weight  $w_{ijs,t}$  is the inverse of the coefficient of variation (CV),

$$w_{ijs,t} = CV_{ijs,t}^{-1} = \hat{f}_{ijs,t} / s_{ijs,t}$$
(2)

 $s_{ijs,t}$  is the standard error of the estimate. The  $CV^{-1}$  is used instead of the inverse of variance, because the mean tends to scale with variance. Low values for  $\hat{f}_{ijs,t}$  are noisy and less important than high values, which are emphasized by the CV.

Following Qiu *et al.* (2022), species seed productivity (SSP) comes from the expectation of all ISP for a given species s:

$$SSP_s = \frac{\sum_{ij} w_{ijs} ISP_{ijs}}{\sum_{ij} w_{ijs}}$$
(3)

where  $w_{ijs}$  is defined the same way as  $w_{ijs,t}$ , i.e., root mean predictive variance divided by the mean ISP for tree *ijs*.

Generalized joint attribute modeling (GJAM) To partition the expected effects that one trait can have on the observations of other traits (eq. (4)), we start with the joint distribution of Mtraits from a species *s* fitted with GJAM, all the traits were log-transformed before entering the model,

$$[\mathbf{T}_{s}|P, X] = MVN_{M}(\mathbf{T}_{s}|\mathbf{B}'\mathbf{x}_{s} + \mathbf{g}[s], \Sigma)$$
$$\mathbf{g} \sim MVN(\mathbf{0}, \Omega)$$
(4)

(Clark *et al.*, 2016), where *MVN* is the multivariate normal distribution,  $\mathbf{g}[s]$  is a random vector for the phylogenetic group to which *s* belongs, and  $\Omega$  is the *M* × *M* covariance between traits taken over phylogenetic groups. With this fitted model, we consider the effects of trait *m* on all other traits, organized in the vector  $[\mathbf{T}] = [\mathbf{T}_{-m}, T_m]$ . Following Qiu *et al.* (2021b), we can partition the mean and covariance as

$$\mathbf{B} = \begin{pmatrix} \mathbf{B}_{-m} \\ \mathbf{B}_{m} \end{pmatrix}$$
(5)

where  $\mathbf{B}_m$  holds column *m* and  $\mathbf{B}_{-m}$  holds the other M - 1 columns of **B**. The covariance matrix is also partitioned as

$$\Sigma = \begin{pmatrix} \Sigma_{-m,-m} & \Sigma_{-m,m} \\ \Sigma_{m,-m} & \Sigma_{m,m} \end{pmatrix}$$
(6)

- This joint distribution allows us to isolate the contributions of trait m as a conditional distribution.
- Subtracting the random effect for species s gives the trait vector  $\tilde{\mathbf{T}}_s = \mathbf{T}_s \mathbf{g}[s]$ . Then

$$\tilde{\mathbf{T}}_{-m,s}|T_{m,s} \sim MVN(\boldsymbol{\mu}_{-m,s}, \mathbf{P})$$
(7)

 $\boldsymbol{\mu}_{-m,s} = \mathbf{B}_{-m}\mathbf{x}_s + \mathbf{A}(T_{m,s} - \mathbf{B}_m\mathbf{x}_s)$ 

$$= \mathbf{C}\mathbf{x}_s + \mathbf{A}T_{m,s} \tag{8}$$

$$\mathbf{P} = \Sigma_{-m,-m} - \mathbf{A}\Sigma_{m,-m} \tag{9}$$

- There are now two sets of coefficients, a length M 1 vector for effects of m,  $\mathbf{A} = \sum_{-m,m} \sum_{m,m}^{-1}$ ,
- and another  $M 1 \times Q$  matrix for effects of  $\mathbf{x}$ ,  $\mathbf{C} = \mathbf{B}_{-m} \mathbf{A}\mathbf{B}_m$ . The elements of matrix  $\mathbf{A}$  are
- arrows in figure fig. 3. Matrix A were obtained with the conditionalParameters function in
- the GJAM package (Qiu *et al.*, 2021b).

**Figure S1:** PCA as presented on Fig. 3 extended with contributions and loadings of the three axes that explained the most variance. A) Species seed productivity (SSP) on the global spectrum of tree form. Arrow length indicates the loading of each considered functional trait onto PCA axes. Points represent the position of species. B) Explained variance for each principal component. Bar plots present the contribution (C,D,E) and loading (F,G,H) of each trait to each principal component. The large point shows the mean position for each group.

**Figure S2:** A) Seed number on the spectrum of tree form. Arrow length indicates the loading of each considered functional trait onto PCA axes. Points represent the position of species. B) Explained variance for each principal component. Bar plots present the contribution (C,D,E) and loading (F,G,H) of each trait to each principal component. The large point shows the mean position for each group.

**Figure S3:** Conditional relationships between traits after accounting for climate but not shared ancestry. Marginal posterior distributions are shown as boxes that contain median vertical lines and are bounded by 68% credible intervals (CI), with 95% CI whiskers. Fig. 3 summarizes the significant relationships.
